7. Abstract

A multiphase program was initiated in 1994 to test commercially available melter technologies for the vitrification of the low-level waste (LLW) stream from defense wastes stored in underground tanks at the Hanford Site in southeastern Washington State. Phase 1 of the melter demonstration tests using simulated LLW was completed during fiscal year 1995. This document is the 100 kg melter offgas report on testing performed by GTS Duratek Inc. in Columbia, Maryland. GTS Duratek (one of the seven vendors selected) was chosen to demonstrate Joule heated melter technology under WHC subcontract number MMI-SVV-384215. The document contains the complete offgas report on the 100 kg melter as prepared by Parsons Engineering Science Inc. A summary of this report is also contained in the "GTS Duratek, Phase 1 Hanford Low-Level Waste Melter Tests: Final Report" (WHC-SD-WM-VI-027).

Confirmation letter on file at WHC granting permission to publish the report of Triangle Laboratories and Parsons Engineering Science, Inc., and GTS Duratek.

EXECUTIVE SUMMARY

Source testing was conducted on the 100 kg melter operated by Catholic University's Vitreous State Laboratory. The testing was conducted during a pilot-scale study involving the vitrification of sludge. Particulate matter emission rates were highest at the melter exhaust and averaged 0.29 lb/hr. At the HEPA filter exhaust, the particulate matter emission rate averaged 0.004 lb/hr. Metals concentrations and emissions rates were measured at the melter exhaust and at the HEPA filter exhaust. The highest metals concentrations were observed in the melter exhaust while the HEPA filter exhaust was virtually clean with most metals reported by the laboratory as non-detectable. Sodium was the most prevalent metal in the melter exhaust (3866 μg/dscf).

Continuous emissions monitoring results for NO_x, SO_2, CO, and THC identified NO_x as the pollutant most prevalent at all of the sampling locations (melter exhaust, post-scrubber, post-demister, HEPA filter). The highest NO_x measurement observed was at the post-scrubber and was 5234 ppmv. However, NO_x measurements were biased by the presence of high concentrations of ammonia in the exhaust gas. Ammonia converts to NO when subjected to the NO_x measurement systems heated converter. NO_x measurements will be biased by 80 percent of the ammonia concentration in the gases to be measured.

Other pollutants were not present in significant quantities when compared to the NO_x concentrations. CO, THC, SO_2 were generally observed at levels below 100 ppmv. Baseline concentrations of NO_x, SO_2, CO, and THC at all locations were below 2 ppmv.

SECTION 1

INTRODUCTION

This sampling and analysis report has been prepared by Parsons Engineering Science, Inc. (Parsons ES) for a source assessment program conducted on an experimental glass melter, operated by the Vitreous State Laboratory (VSL) of the Catholic University of America. The Director of the VSL is Dr. Pedro Macedo. This pilot-scale melter (100 kg) is located in Hannon Hall, Catholic University of America, Washington D.C., 20064. Process sampling results are presented and summarized in this report. Collected data will be used by the VSL as part of the performance evaluation program for the 100 kg melter.

During this source assessment, Parsons ES monitored the melter at different locations of the process and air pollution control system. Emission rates of sodium (Na), potassium (K), cesium (Cs), strontium (Sr), molybdenum (Mo), boron (B), and chromium (Cr) were measured. Particulate matter emission rates were also measured. Parsons ES periodically monitored several gas streams for nitrogen oxides (NO_x), sulfur dioxide (SO_2), carbon monoxide (CO), oxygen (O_2), and total hydrocarbons (THC).

The physical design and layout of the 100 kg melter prevents strict adherence to the source test methodologies prescribed by 40 CFR Part 60, Appendix A for compliance monitoring. Therefore, we modified the EPA Reference Methods of 40 CFR Part 60 and utilized other EPA source test methods to conduct a source assessment program of the 100 kg melter; these modifications were made to allow collection of samples in the most representative manner as possible, given the nature of the physical constraints of the system layout.

The 100 kg melter source assessment was conducted by a Parsons ES field crew of two engineers and two senior technicians with the assistance of VSL operators, on September 26 and 27, 1994. Analysis of samples for metals content was performed by Triangle Laboratories, Inc.

This page intentionally left blank.

SECTION 2

SOURCE DESCRIPTION

The 100 kg melter is an electrically-powered melter designed to vitrify certain types of hazardous materials of varied natures. During this testing, a surrogate sludge was fed to the melter to simulate the low-level radioactive or mixed waste for which this melter is being designed. Once the desired glass composition in the melter was obtained, the melter operated continuously for approximately three days, during which time the surrogate sludge was pumped into the unit. Source testing occured during the first twenty-seven hours of the melter demonstration.

The exhaust from the melter is treated by an air pollution control system. Exhaust air leaves the melter at temperatures between 500 and 800° C and passes through a quench and then to a caustic scrubber. Two demisters follow the caustic scrubber and after the gas passes through them, it is re-heated before being sent to a baghouse for final particle removal. Final gas cleaning is accomplished with a HEPA filter. A small volume of ambient air is added to the exhaust air prior to the HEPA filter to control the humidity and maintain HEPA filter performance.

This page intentionally left blank.

SECTION 3

SAMPLING LOCATIONS

Four sampling locations were selected by the VSL for the source assessment of the 100 kg melter. These locations are the melter exhaust, post-quench, post-demister, and HEPA filter exhaust.

The melter exhaust sampling location is pictured in Figure 3.1. A pipe "T" fitting was modified for use as a sampling port in the four-inch i.d. Inconel® pipe that ducts exhaust gas from the melter. The main sampling port is located at a bend, approximately two feet downstream from the melter exhaust stack. Due to the melter equipment arrangement, there are no sampling locations that meet the criteria for isokinetic sampling as described in EPA Reference Method 1 or 1A. Also, the small duct diameter precludes sampling traverses. Instead, a single point nominally in the center of the gas flow, was selected for the sampling nozzle location. An auxiliary sample point was installed downstream of the main sampling point for the collection of NO_x, SO_2, THC, CO, and O_2.

Sampling at the post-quench was performed at a sampling port located just down stream of the quench (Figure 3.2). A small tap suitable for sampling NO_x, SO_2, THC, CO, and O_2 was installed in the six-inch i.d. stainless steel pipe. This location was only used for extraction of samples for the CEM system.

Sampling at the post-demister was performed at a sampling port located just down stream of the demister (Figure 3.3). A small tap suitable for sampling NO_x, SO_2, THC, CO, and O_2 was installed in the eight-inch PVC pipe, prior to the reheat. Like the post-quench, this location was only used for CEM sampling.

The HEPA filter exhaust was sampled at the exhaust pipe after it leaves the filter and before it passes through the induced draft fan (Figure 3.4). The main sample location was selected as required by EPA Reference Method 1A. The exhaust duct is a 5-inch diameter steel pipe with a sampling port for isokinetic sampling located eight diameters downstream from the nearest disturbance and approximately four diameters upstream from the nearest disturbance.

POST-DEMISTER

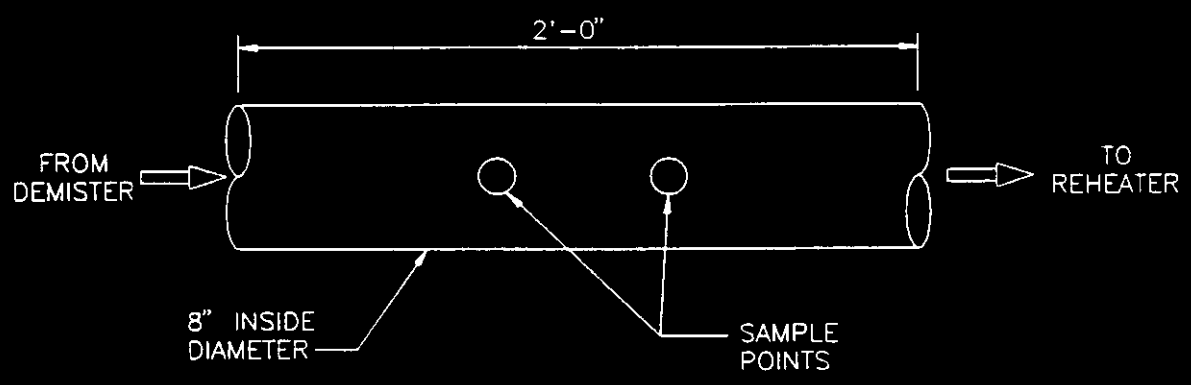

FIGURE 3.4
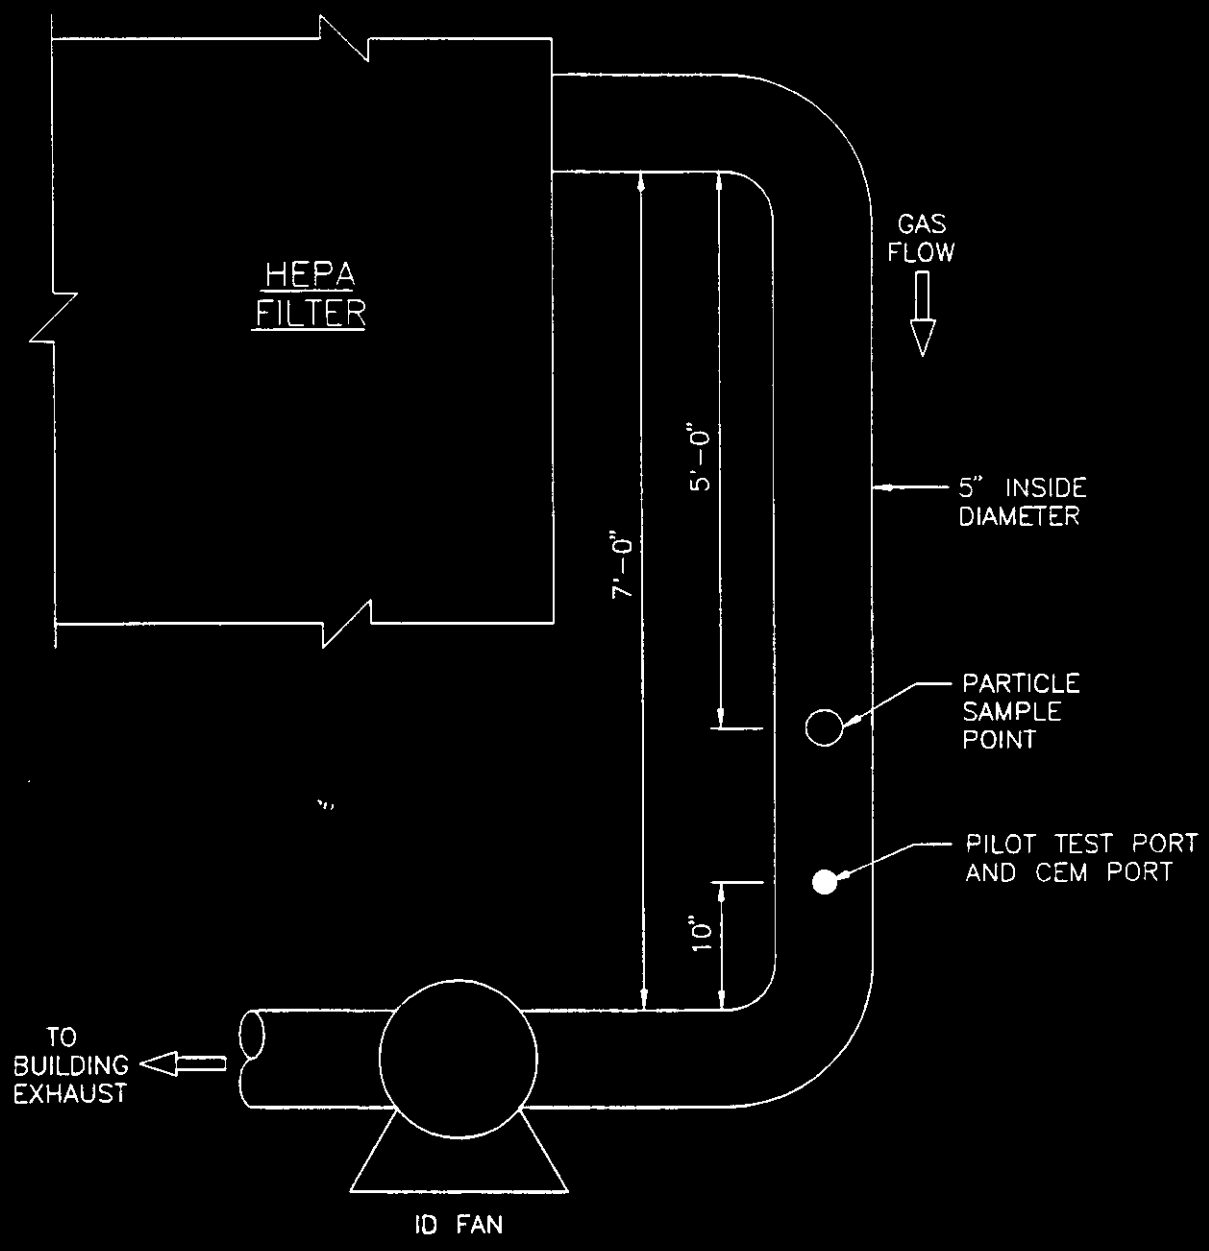
HEPA FILTER EXHAUST



726517/DR4326JB.RPT

26517F04

A pitot tube port was installed downstream of the main sampling port for velocity measurements with a standard pitot tube. As with the Melter Exhaust, a single sample point nominally in the center of the exhaust gas flow, was selected for the sampling nozzle.

The pitot tube port also served as an auxiliary sampling port for non-isokinetic sampling.

SECTION 4

TEST PROGRAM AND SAMPLING METHODS

As stated previously, the purpose of this source assessment program is to provide emissions data for the VSL's 100 kg melter. This test program collected emissions data from four sampling locations: the melter exhaust, the post-quench, post-demister, and HEPA filter exhaust. Particulate matter and metals samples were collected from the melter exhaust and HEPA filter exhaust locations. From all four locations, NO_x, SO_2, THC, CO, and O_2 were measured. Figure 4-1 is the sampling matrix for the source assessment program.

Particulate Matter and Metals Sampling

Particulate matter and metals were collected at the Melter Exhaust with a modification of the multiple-metals method from the ***Methods Manual for Compliance with the BIF Regulations (EPA/530-SW-91-010)***. The BIF metals methods was used in conjunction with EPA Method 1A at the HEPA Filter Exhaust sampling location.

With the BIF Metals Method, particulate and gaseous emissions are isokinetically withdrawn from the stack and collected on a quartz fiber filter and in an impinger solution. Metals in the particulate phase are captured on the filter and vapor-phase metals are collected in the impinger solution. This source assessment program used two impingers each containing 100 ml of a 5% nitric acid/10% hydrogen peroxide solution. The various fractions of the sampling trains are digested prior to analysis by inductively-coupled argon plasma (ICAP) spectroscopy. Generally, this method is used for the sampling and analysis of trace metals. Except for chromium, the metals targeted in this source assessment program are not usually selected for emissions monitoring. However, the selected analytical methodology, ICAP, provides the sensitivity and precision desired.

Prior to metals analysis of the sample filter, the filter was weighed to measure the mass of particulate matter collected.

As mentioned previously, the BIF Metals method was modified to accommodate the sample point configuration at the melter exhaust. Since the exhaust gas temperature

exceeded the softening temperature of a conventional glass probe, the sampling nozzle and sampling probe were made from Inconel®. An equipment blank was collected from the nozzle/probe assembly to check for the possibility of contamination from the equipment.

A summary of the BIF Metals Method is presented in the appendices. Also included in the appendices are the summaries of EPA Reference Methods 1 and 5. These are the standard methods upon which the BIF Metals Method draws for the isokinetic and particle sampling guidelines. The source test protocol provides greater detail of the sampling methods.

CEM

At each of the four sampling locations, the exhaust gas was sampled and analyzed for NO_x, SO_2, THC, CO, and O_2. Stack gas samples for analysis by continuous emissions monitors were extracted from a single point at each sample location. Monitoring at each location was conducted on a rotating schedule that reflected the requirements of the VSL staff. Generally, monitoring was conducted at each location for 10 to 15 minutes of every hour during the testing. Two sample streams were extracted from the stack and transported to the mobile CEM laboratory through the use of self-regulating heated sample lines, which are designed to maintain gas temperature of 250 °F above the ambient temperature. One of the streams was conditioned to remove entrained particles and moisture and then sent to a stainless steel sampling manifold. Continuous samples for the oxygen, carbon monoxide, nitrogen oxide, and sulfur dioxide analyzers were extracted from the manifold, and the excess gases were vented to the atmosphere. The second stack gas stream was not conditioned, and was sent directly to the continuous hydrocarbon analyzer which analyzed the total hydrocarbon content of the sample with a flame ionization detector.

Instrument responses to calibration standards and sample gases were analyzed and recorded by a PC-driven data acquisition system (DAS). The DAS consists of an analog-to-digital signal converter and a personal computer which analyzed the instrument responses and converted the analog signals to the appropriate engineering units. The analyzer responses were read and recorded at thirty-second intervals on the PC's hard disk drive and on a computer print-out.

Stack Gas Oxygen Content

The oxygen content in the effluent gas was measured by a Horiba PMA-200 Paramagnetic Oxygen Analyzer in accordance with the procedures in EPA Method 3A. O_2 was analyzed on a dry basis and the instrument responses were recorded by the DAS. The PMA-200 has two operating ranges, 0 - 10, and 0 - 25 percent oxygen. During this test, the instrument was operated on the 0 - 25 percent range and calibrated with oxygen standards containing approximately 17.7 and 11.2 percent oxygen. Prior to each day of testing, the instrument was calibrated by introducing a zero gas and the upscale calibration standards directly to the analyzer. The sample line bias was checked by introducing the zero gas and the mid-range calibration standard into the sampling system immediately downstream of the probe. The oxygen measurement system response and drift was determined at the conclusion of each sampling run by introducing the zero and upscale calibration standard into the measurement system downstream of the probe.

Stack Gas Nitrogen Oxides Content

The nitrogen oxides content in the effluent gas was measured by a Thermo Environmental Model 10 $NO/NO_2/NO_X$ chemiluminescence analyzer in accordance with the procedures in EPA Method 7E. NO_X in the sample gas is converted to NO and detected by the chemiluminescent reaction with ozone. This analytical procedure is subject to interference from NH_3. There was an unanticipated elevated amount of NH_3 in the exhaust from the source tested. NH_3 concentrations were estimated to be as high as 2,000 ppmv which is significant since as much as 80 percent of that concentration can bias the NO_X measurements. NO_X was analyzed on a dry basis and the instrument responses were recorded by the DAS. The Model 10 has eight operating ranges, 0 - 2.5, 10, 25, 100, 250, 1,000, 2,500, and 10,000 ppm nitrogen oxides. During this test, the instrument was operated on the 0 - 250 ppm range and the zero to 1,000 ppm range and calibrated with nitric oxide standards containing approximately 225 and 150 ppm nitrogen oxide. The instrument was calibrated by introducing a zero gas and the upscale calibration standards directly to the analyzer. The sample line bias was checked by introducing the zero gas and the mid-range calibration standard into the sampling system immediately downstream of the probe. The nitrogen oxides measurement system response and drift were subsequently determined at the conclusion of each sampling run by introducing the zero and upscale calibration standard into the measurement system downstream of the probe.

Stack Gas Total Hydrocarbon Content

The THC content in the effluent gas was measured by a J.U.M. VE-7 Total Hydrocarbon Analyzer in accordance with the procedures in EPA Method 25A. Hydrocarbons in the sample stream were measured continuously by a Flame Ionization Detector. THC was analyzed on a wet basis and the instrumentation responses were recorded by the DAS. The VE-7 has five operating ranges, 0 - 10, 100, 1,000, 10,000 and 100,000 ppm hydrocarbons, and is calibrated using propane standards that correspond to approximately 30, 60, and 85 percent of the full-scale response. The VE-7 was operated at the 0-100 ppm range. Prior to testing, the instrument was calibrated by introducing a zero gas and the upscale calibration standards into the sampling system directly downstream of the sample probe. The THC measurement system response and drift were determined at the conclusion of each sampling run by introducing the zero and upscale calibration standard into the measurement system downstream of the probe.

Stack Gas Sulfur Dioxide Content

SO_2 measurements were made using the procedures outlined in EPA Method 6C. Method 6C is based on absorption of ultraviolet radiation by the SO_2 molecule. The amount of light absorbed is dependent upon the concentration of the compound present. The UV light beam is split after the light source, with one part passing through the sample cell, and the other part passing through the reference cell, which is filled with a non-absorbing gas. Each beam then passes through a narrow band pass filter into photomultiplier tubes for creation and amplification of the signals. The amount of absorbed light (found by difference in signal intensity) is proportional to the amount of absorbing species present.

The SO_2 analyzer used is a Horiba that operates on the principle of UV absorption. The analyzer has full-scale ranges of 0 to 100 and 0 to 500 ppm. SO_2 standards are SO_2 in air and are selected to correspond to approximately 55 and 85 percent of the instrument span range.

Summaries of the sampling methods are provide in the appendices.

Sampling Schedule

The source assessment program was conducted over two days, on September 26 and September 27, 1994. Three metals and three particle runs were conducted at both the melter exhaust and at the HEPA filter exhaust. Each metals sampling run lasted for approximately one hour. Metals samples were collected simultaneously at each location.

Exhaust samples each of the four sampling locations were directed to continuous emissions monitoring instruments at 15 minute intervals. After monitoring for approximately 15 minutes at each location , the exhaust from the next location was sampled. During each run, the first location monitored was the HEPA filter exhaust. The next location from where sample was drawn was the post-demister, then the post-scrubber, and finally the melter exhaust.

SECTION 5

QA/QC PROCEDURES

The main quality assurance and quality control (QA/QC) procedure for the 100 kg melter source assessment is the adherence to the test protocol. By following the approved source test protocol, complying with the applicable QA procedures for each sampling and analysis method, and documenting changes to the protocol, the quality of resulting performance test data can be evaluated.

Sampling Equipment

Further QA/QC is provided for by the routine calibration and maintenance of the stack testing equipment. All stack sampling equipment to be used in this testing effort is periodically calibrated according to the methodologies and frequencies established in the EPA Quality Assurance Manual. Routine maintenance dictated by the Quality Assurance Manual and good engineering practice ensures quality performance of the sampling equipment. Prior to field use, source test equipment is checked for proper performance and valid calibrations. Upon completion of a source test program, sampling equipment calibrations are re-checked to assess equipment performance during the source test.

Meter Boxes

Meter boxes used for source testing are subjected to multi-point calibrations once each year, or after repairs are made to the dry gas meter, orifice, or thermocouples. Meter boxes are assigned a unique ID number, and a calibration performed on meter boxes are recorded in the notebook. The dry gas meter and orifice are calibrated at five flow settings ranging from an orifice pressure of 0.5" WC to 4.0" WC. The meter box calibration factor (gamma,) is calculated for each flow setting and checked to ensure that no individual gamma differs from the average by more than 0.02. Similarly the ΔH@ value of the orifice is calculated for each flow setting and checked to ensure that no individual value differs from the average by more than 0.15. Dry gas meter thermocouples are checked against a mercury-in-glass thermocouples are considered unacceptable and are repaired or replaced if they do not read within 5.4°F at each of the calibration points.

Pitot Tubes

Standard pitot tubes are checked for conformance to the dimensional criteria described in Method 2 as they are received, and assigned a pitot tube coefficient, C_p, of 0.99. The pitot tube is checked prior to and at the conclusion of each sampling program for which the pitot tube is used.

Thermocouples

Stack temperature thermocouples are permanently attached to the sampling probes and are checked as received for accuracy. The thermocouples are checked against a mercury-in-glass thermometer at three temperatures: ice-point, ambient, and boiling H_2O point. Calibration and maintenance data for each stack thermocouple are recorded in the appropriate sampling probe notebook. Probe liner, filter box, sample gas, and condenser thermocouples are checked for accuracy at three water temperatures: icepoint, ambient, and boiling point. Parsons ES recognizes that the temperature of the probe liner, heated sample box, and sample gas temperature are generally maintained at temperatures of approximately 250°F. Since these temperatures are not used to calculate stack gas parameters or correct sample volumes, the calibration procedure is considered adequate when weighed against the danger of working with boiling oil. Each thermocouple is assigned a unique identification number and a notebook for recording calibration and maintenance data.

Sampling Nozzles

Parsons ES maintains a full range of sampling nozzles to conduct isokinetic sampling at a variety of exhaust gas velocities. Nozzles are stored in padded metal boxes to prevent damage during storage or transport. The internal diameter of the nozzle is measured using a set of dial, electronic, or vernier micrometer. The diameter used to calculate the nozzle area is determined from the average of three measurements of the nozzle in three different diameters. The nozzle is not used if an individual diameter differs from the average by more than 0.004 inch.

Summary (Table)

A summary of sampling equipment with corresponding calibration procedures, frequencies, and acceptance criteria can be found in Table 5-1.

Analytical Balances

Analytical balances are professionally cleaned and calibrated annually by certified balance technicians provided by the manufacturer. Following this professional calibration, a document is provided by the manufacturer, stating the model number, serial number and date of calibration. Additionally, a sticker noting the technician's name and the date of calibration is attached to the balance.

Each time the balance is used, a calibration check is performed using a set of Class S weights. The results of each calibration are recorded in a notebook which remains with the balance being used.

Continuous Emissions Monitors

The quality of collected CEM data is ensured by the adherence to the calibration and maintenance programs specified by the instrument manufacturers and in the EPA Reference Methods used during the monitoring. Calibration procedures are provided in greater detail in the appendices.

TABLE 5-1

CALIBRATION OF SAMPLING EQUIPMENT

Apparatus	Acceptable Limits	Frequency and Methods of Measurements	Corrective Action
Wet Test Meter (64 ft^3/hr cap.)	Y=1.00±0.01 for calibration range 7.5 to 65 ft^3/hr	Initially and annually by bell prover	Return to service center for corrective maintenance
Dry Gas Meter	Y tolerance for individual values ± 0.02 from average Y value	Calibration initially and annually against calibrated wet test meter at 0.50, 0.75, 1.0, 1.5, 2.0, and 4.0 in H_2O	Repair or replace as needed, recalibrate over full range of flow settings
	$Y_f = Y_i \pm 0.05Y_i$	Post-test calibration check after field use	Repair or replace as needed, recalibrate over full range of flow settings
	ΔH@ tolerance for individual values ± 0.20 from average ΔH@ value	Calibration initially and annually against calibrated wet test meter at 0.50, 0.75, 1.0, 1.5, 2.0 and 4.0 H_2O	Repair or replace as needed, recalibrate over full range of flow settings
Stack Thermocouple	1.5% of absolute temperature as indicated by ASTM mercury-in-glass thermometer	Initially and annually at ice-point, and boiling water point. Temperatures extrapolated to 1500°F	Adjust, determine calibration factor, or reject
Filter Heater Thermocouple	± 5.4°F as indicated by ASTM mercury-in-glass thermometer	Initially and annually at ice-point and boiling water point	Adjust, determine calibration factor, or reject
Condenser Outlet Thermocouple	± 2°F as indicated by ASTM mercury-in-glass thermometer	Initially and annually at ice-point and boiling water point	Adjust, determine calibration factor, or reject

SECTION 6

RESULTS AND DISCUSSION

This section provides the sampling results and discussion of the collected data. Results are presented in tables and summarized in the text. Field data, laboratory reports, and computer calculations are presented in the appendices.

Exhaust gas characteristics were observed to be very different at each sample location. The greatest differences were noted between the melter exhaust and the HEPA filter exhaust. Melter exhaust had a much higher particle mass loading than the HEPA filter exhaust. These differences are large enough that sample analysis and data evaluation procedures had to vary for the two locations. For example, the probe washes collected from sample trains used at the melter exhaust contained high concentrations of particle matter in the nitric acid portion of the rinsate. This was not observed for the HEPA filter exhaust samples. Therefore, part of the analytical procedure for the melter exhaust samples was a filtration of the nitric acid rinsate and gravimetric analysis of the particle mass retained on the filter. This procedure was not necessary for the HEPA filter exhaust samples because the particle concentrations and emission rates are extremely low.

HEPA filter exhaust samples were so clean that analytical results for many of the metals were below the instrument detection limits, just as the method reagent blanks. This is a difference from the results observed for the melter exhaust which had measurable concentrations of metals. Final results from the two sample locations were therefore treated differently. The melter exhaust samples were blank corrected while the HEPA filter exhaust samples that were below instrument detection limit were not. The reason for this was to avoid reporting "zero" emissions from the HEPA filter exhaust. A conservative approach is to consider the blanks as zero and then use the instrument detection limit for the metals results that the laboratory reported as non-detectable. Emission rates and concentrations are then reported as "less than" a value.

In the appendices to this report are the details of the analytical procedures and data handling procedures used in this project.

Particulate Matter Concentrations and Emission Rates

Particulate matter sampling results are provided in Tables 6.1 and 6.2. Table 6.1 provides the emission rates for the melter exhaust sampling location and Table 6.2 shows the HEPA filter exhaust sampling results.

The average particulate matter concentration and emission rate measured at the melter exhaust location was 0.43 gr/dscf and 0.29 lb/hr, respectively. At the HEPA Filter Exhaust location, the measured concentrations and emission rates averaged 0.0024 gr/dscf and 0.0040 lb/hr, respectively. The maximum emission rate measured was 0.50 lb/hr for Run #3 at the melter exhaust. The greatest grain loading observed, 0.75 gr/dscf, was also for Run #3 and from the melter exhaust location.

Because of the heavy particle loading in the melter exhaust and the possibility of incomplete sample recovery, an equipment blank was collected during the test program to evaluate the bias introduced by the sample train cleaning procedure. The equipment blank constituted a full sample train designated for use at the melter exhaust location. It was carried to the sample location, and then recovered and analyzed like a regular sample. The front half portion of the equipment blank showed a net weight gain of 0.0226 grams or 4.5% of the smallest sample weight observed for the Melter Exhaust (Run #2). This slight bias has not been applied to the melter exhaust sample results shown in Table 6.1. What the field blank demonstrates is that there is some bias (+ or −) in the particulate measurements due to the sampling methodology.

Another source of bias in the melter exhaust particulate emission rate measurements has been introduced because the melter exhaust sampling location does not meet either EPA Method 1 or EPA Method 1A isokinetic sampling location criterion. The velocity profile at this location is not well-characterized so an evaluation of the bias must begin with the melter exhaust system. Melter exhaust gas exits the furnace in a four-inch internal diameter pipe at a flowrate of roughly 177 acfm with an approximate velocity of 35 f/s.

The sample location is located at a disturbance, as described in Section 3, and six pipe diameters upstream of the sample location is another disturbance. Furthermore, the surface area of the sample nozzle exposed to the gas flow is large enough to introduce disturbance to

the flow of exhaust gas past the sampling nozzle. This suggests that the turbulent flow has eddies that can disrupt streamlines and bias the sample collection of particles with varying diameters.

Isokinetic sampling is designed to collect sample gas through the sampling nozzle at the same velocity the gas has in the stack. If the stack gas velocity is constantly changing at the sample nozzle due to eddies or an otherwise unsteady flow, than the sampling rate for collecting particulate matter may not be correct during some periods of testing. If gas samples are not collected at the isokinetic rate then the particulate matter measurements will be biased. The direction of the bias, whether it increases or decreases measured emission rates, depends on whether the particulate matter samples were collected at a rate greater or lesser than the desired isokinetic sampling rate. The bias direction also depends on the sizes of the particles being sampled. If you are collecting samples at a faster rate than required, then the larger diameter particles will be under-represented in the measurement.

Also, the melter exhaust flowrate was not observed to vary significantly, suggesting that the main cause of varying velocities at the nozzle location would be eddies in the gas flow. Smaller diameter particles are generally over represented in the collected samples if the sample collection rate is greater than isokinetic.

Metals Concentrations and Emission Rates

Tables 6.1 and 6.2 show the exhaust gas metals concentrations and emission rates. Emission rates and concentrations for the melter exhaust are shown in Table 6.1. Na, K, B, and Cs are present in the highest concentrations and have the greatest emission rates. The average emission rate for these compounds was 4.02 E-02 lb/hr, 1.88E-02 lb/hr, and 1.2E-02 lb/hr, and 6.43E-03 lb/hr. Concentrations of Na, K, B, Cs averaged 3,866 ug/dscf, 1818 ug/dscf, 1125 ug/dscf, and 624 ug/dscf. The Na concentration is 14.4% of the total suspended particle (TSP) concentration; the K concentration is 7.48% of the TSP concentration; B is 3.97% of the TSP particle concentration; and Cs is 2.4%. Cr, Mo, and Sr were found in the melter exhaust samples, but at significantly lower concentrations relative to Na, K, B, or Cs.

The metals concentrations measured at the melter exhaust may be biased by the sample location for the same reasons that particle concentrations may be biased. Metals that are

associated with particulate matter may have been overestimated or underestimated due to the physical dimensions of the sampling location, as described previously.

Exhaust gas samples collected after the HEPA filter contained mainly Na, K, and B (Table 6.2). The Na, K, B concentrations averaged <70 ug/dscf, <40 ug/dscf, and <125 ug/dscf. These averages have been blank corrected by subtracting the blank from the sample value and then taking the negative result and multiplying it by two and using the absolute value as a sample result. The calculated concentrations are then reported as "less than" values. It is likely that any Na, B, or K found in the HEPA filter exhaust is due to the glass filter and reagents, since the blank levels and sample levels are close in values.

The concentrations of Sr, Mo, Cr, and Cs are small compared to the concentration of the other metals. Sr, Mo, Cr, and Cs are present in the samples at concentrations that are either less than the detection limit or less than the reagent blank value. Emission rates and concentrations of Sr, Mo, Cr, and Cs presented in Table 6.2 are based on analytical results reported as less than the detection limits and they have not been blank corrected. This method of calculation provides an overestimate of the emission rates and concentrations.

Continuous Emissions Monitoring Results

Table 6.3 provides a summary of the CEM measurements made at each sample location. Exhaust gas from the melter was measured at each location prior to introducing any feed to the melter. These measurements are refered to as "baseline" measurements or concentrations. Baseline concentrations of NO_x, SO_2, CO, and THC were measured in the melter exhaust as less than ppmv. Measured NO_x concentrations ranged from 584 ppmv to 1336 ppmv, at the HEPA filter exhaust. NO_x concentrations at the melter exhaust varied from 2552 ppmv to 3610 ppmv. (As discussed previously, these measurements were biased upwards because of sample matrix interference). SO_2 concentrations ranged from a minimum of 0.2 ppmv at the HEPA filter exhaust to a maximum of 67.2 ppmv, at the Melter Exhaust. THC concentrations varied from 5.2 ppmv at the HEPA filter exhaust to a maximum of 32.4 ppmv at the melter exhaust. Measured CO concentrations were observed as high as 116 ppmv at the Post-Demister. O_2 concentrations did not change significantly from the 20.9% considered representative of ambient concentrations.

* N.D. denotes no data.

1 The NO_x concentrations are biased by the high concentration of NH_3 present in the melter exhaust. The values are approximately 80 percent too high.

The design of the melter's air pollution control system had an impact on the pollutant concentrations observed at the HEPA filter exhaust. Ambient air is mixed with process exhaust prior to its passing through the HEPA filters, diluting the exhaust gas with ambient air prior to its being measured by the CEM system. The reduced values of NOx, CO, SO2, and THC observed at the HEPA filter exhaust are due to the dilution by the ambient air.

NO_x measurements collected at each location were biased upwards because of sample matrix interference with the NO_x analyzer. Furthermore, during the testing of the 100 kg melter, some differences between the Parsons ES CEM data and the VSL portable analyzer were noted. There was no immediately apparent reason for these differences. Since then, we have reviewed the data, discussed the instrumentation response with manufacturers' technical representatives, and come to some conclusions regarding the data. Basically, the oxygen, carbon monoxide, sulfur dioxide, and total hydrocarbon data are valid as collected and show that the melter emissions were seldom constant, changing over time, sometimes, quite rapidly.

Of most concern, and the most obvious differences between the portable and Parsons ES CEM instruments, were the NO_x readings. Apparently, although we do not have any of VSL-collected data, the VSL results were sometimes an order of magnitude lower than the Parsons ES data at the HEPA filter exhaust. Some readings obtained by Parsons ES were as high as 2500 ppmv, before correction for drift and calibration error and almost 3500 ppmv after correction. The tremendous range of observed reading (0-5200 ppmv) creates its own set of problems relating to analyzer calibration at the proper range. These problems were remedied after the high readings were observed. It now appears, from discussions with VSL personnel and manufacturer personnel, that much of disparity between Parsons ES and VSL data may come from NH_3.

Parsons ES uses a TECo Model 10 chemiluminescence analyzer with a stainless converter for the NO_2 to NO conversion. The manufacturer states that this converter will also convert NH_3 to NO at 80-85% efficiency up to 2000 ppm by volume NH_3. Further, the relatively high concentration of NH_3 would essentially contaminate the converter for some period of time. According to Dr. Matlack, it is entirely possible to have 2000 ppm or higher of NH_3 in the flue gas. We do not have sufficient data to determine the interference level any more precisely than this.

There are several possibilities for doing so, however. The NOx analyzer can be run by bypassing the converter. This is usually done to differentiate between NO and NO2, so the presence of large concentrations of NH_3 in the gas stream would have an unknown effect on the chemiluminescence reaction and on the components themselves. We could also put an ammonia scrubber ahead of the analyzer and compare the scrubbed with the unscrubbed results. A proper experiment would need to address other interferences and analyte removal or conversion processes. The third possibility is to use a NOx analyzer with a molybdenum converter. The MolyCon converts only 5-6% of the ammonia to NO and thus would reduce but not eliminate the interference problem.

< Means that the entry to the left was listed in the laboratory data report as less than the given value. For conservatism, the number shown was used in calculations.
*Means that blank-adjusted value is not being used in emissions calculations for these metals.
Blank corrected values that are negative have been: multiplied by two and then the absolute value was used to calculate concentrations and emissions.
The resulting values are reported as "less than" values.

VOLUMETRIC FLOW RATE BY METHOD 2

Summary of Method

Method 2 is a procedure for measurement of the average velocity head and temperature of a gas stream at discrete locations within the duct that are representative of the total gas flow. The density of the gas must be known before the data collected can be used to calculate the volumetric flow rate of the gas. The density of the exhaust gases of combustion sources may be determined by measuring the oxygen and carbon dioxide (by Method 3 or 3A) and moisture (by Method 4) concentrations of the gas.

The velocity head, the difference between the impact pressure and the static pressure of the gas, can be measured with either a standard Pitot tube or an S-type Pitot tube. Either of these devices may be used without calibration if their construction conforms to certain geometric criteria. A properly constructed standard Pitot tube will overestimate the total velocity head by 1 percent, and a properly constructed S-type Pitot tube will overestimate the total velocity head by 19 percent. When the velocity of the stack gas is calculated, a correction appropriate to the type of Pitot tube used is made. In both cases, the error is due to static pressure decrease in the turbulent wake behind the impact pressure tap.

Description of Sampling Equipment

The velocity head is measured by the Pitot tube and an oil-filled manometer. The stack gas temperature is measured by a type-K thermocouple. The temperature is displayed by a digital temperature readout that is electronically compensated for ambient temperature. Figure 1, which shows an entire Method 5 sampling train, also shows the Pitot tube and manometer system.

Description of Operation

Prior to recording velocity and temperature data, the gas in the duct must be checked to ensure straight (non-cyclonic) flow with respect to the duct centerline. The Pitot tube is inserted into the duct with the faces perpendicular to the duct cross-section. A reading of zero pressure differential at each of the sampling points indicates non-cyclonic flow.

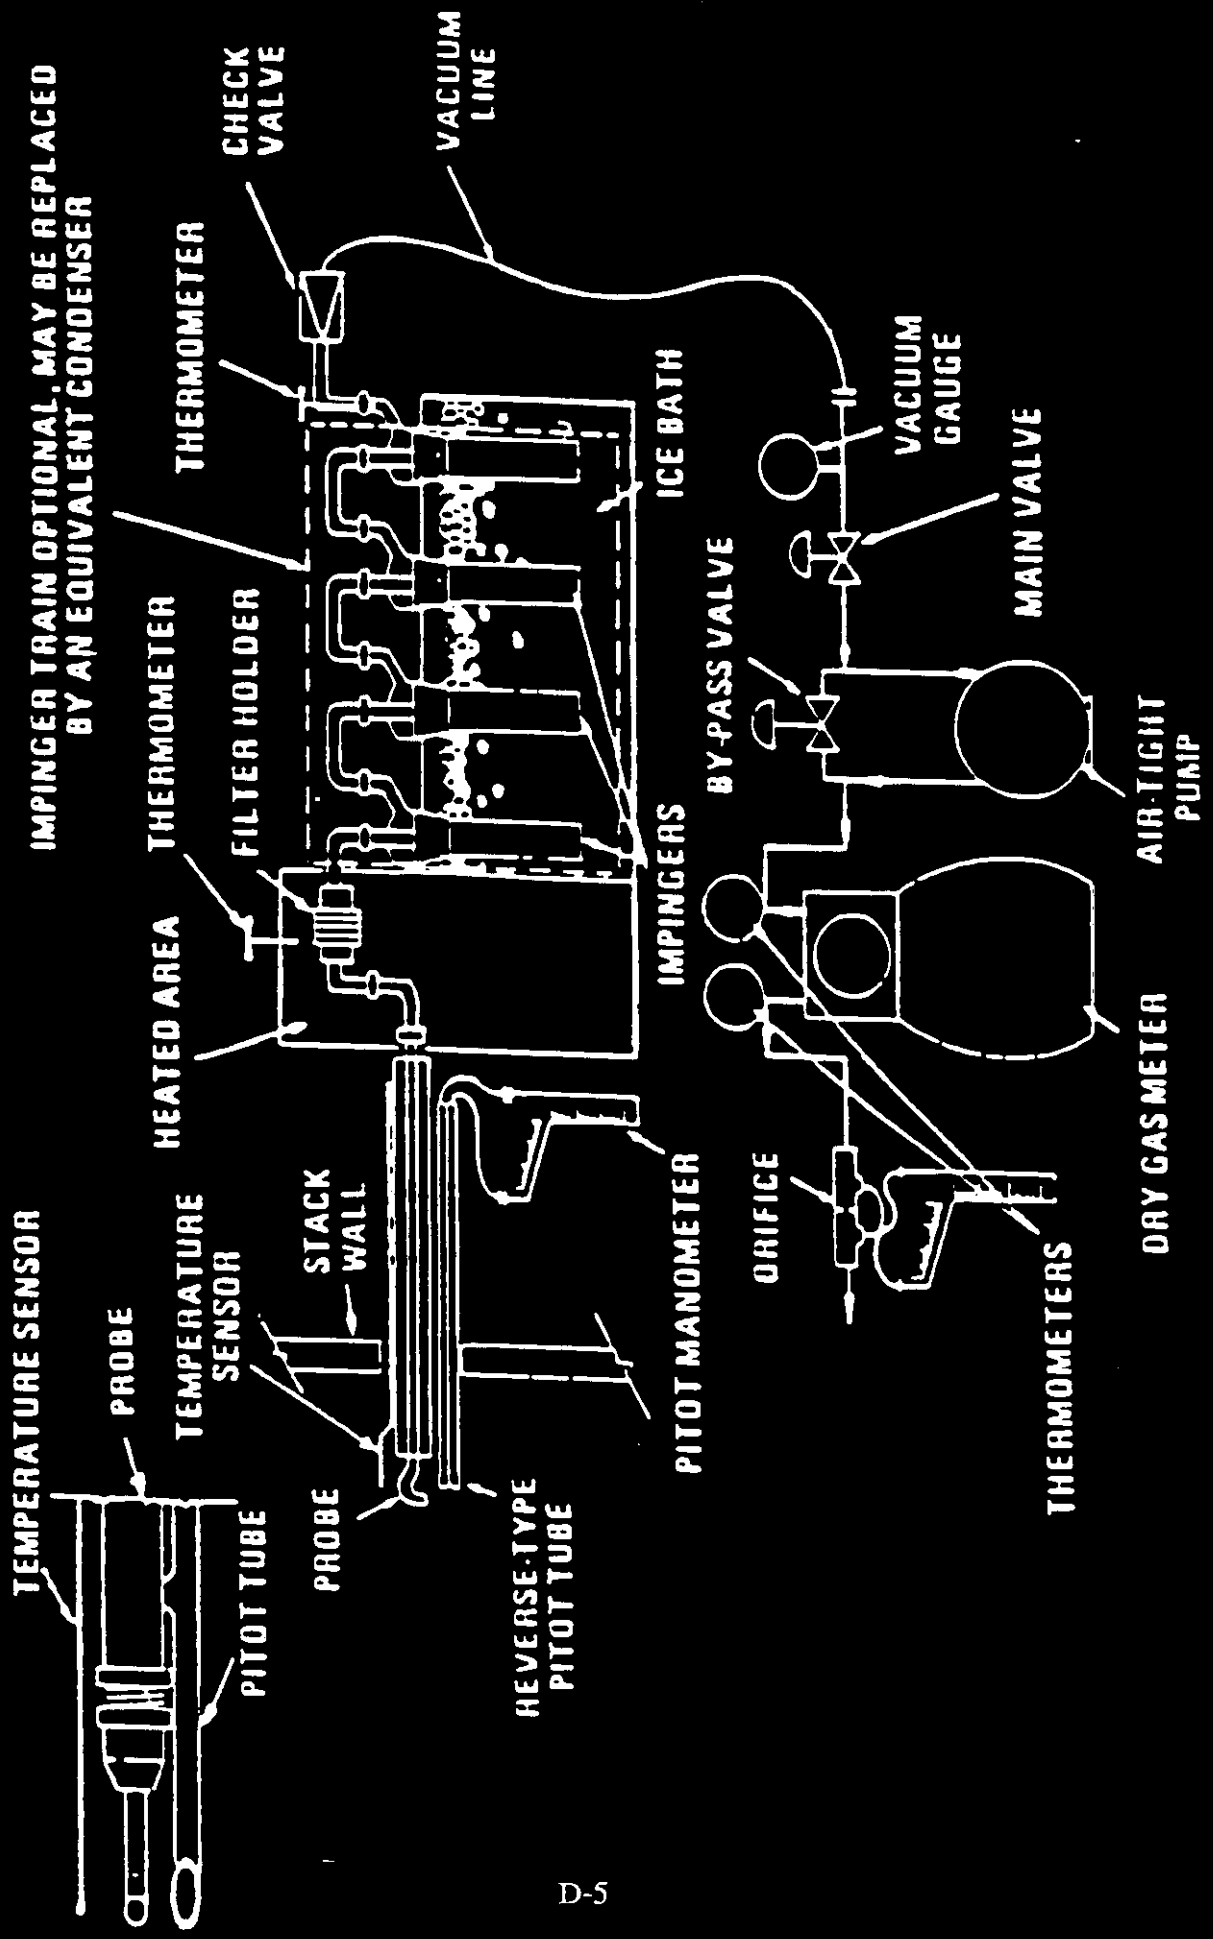

FIGURE 1

METHOD 5 SAMPLING TRAIN

726517/GH4298SA.APP

During testing, the velocity head and temperature at each sample point, the static pressure of the duct, and the absolute barometric pressure are recorded.

Description of Leak Check Procedures

Before reading of the gas velocity pressure one made, the pitot-manometer system is leak checked. A short length of flexible tubing is attached to the impact side of the pitot tube, and a pressure of five to seven inches of water is put on the system by month. The tubing is crimped and the manometer is observed. The leak check is considered successful if the pressure holds steady for fifteen seconds. The process is then repeated on the static side of the system, however in this instance five to seven inches of water vacuum is placed on the system.

Description of Detection Limits

The minimum differential pressure that can be accurately measured with the standard 0" to 10" inclined manometer is 0.01" water. If more than 10 percent of the velocity head values are, or if the average value is, less than 0.10" then a more precise manometer must be used. The minimum velocity that can be measured with a Pitot tube is approximately 10 ft/sec. Below this value the assumptions about turbulent flow upon which the Bernoulli equation is based fail and the calculation becomes inaccurate.

Temperature is measured with a type-K thermocouple. These devices are accurate to ±3°F over a range from 0°F to 1500°F.

Calibration Procedures

Pretest calibration of the S-type Pitot tube consists of measuring the angles and dimensions of the measuring tip and making adjustments as required to ensure that it conforms to standards specified in Method 2.

The thermocouple is calibrated at the ice point and boiling point of water and at an upscale, hot oil, temperature against a mercury-in-glass thermometer.

CO_2 AND O_2 CONCENTRATION BY METHOD 3A

Summary of Method

This method uses an electronic continuous emission monitor (CEM) to measure both CO_2 and O_2 concentrations. Analysis of carbon dioxide is based upon the absorption of infrared radiation by the carbon dioxide molecule. The intensity of the absorption depends on the concentration of CO_2 compound present. The infrared light beam is split after the light source, with one part passing through the sample cell, and the other part passing through the reference cell, which is filled with a non-absorbing gas. Each beam then passes through a narrow band pass filter which passes the wavelength of light corresponding to the most intensely absorbing vibration into a photomultiplier tube which amplifies the signal. The amount of absorbed light (found by difference in signal intensity) is proportional to the amount of absorbing species present.

The method of analysis for O_2 is based upon the electrochemical reaction of oxygen in a fuel cell which occurs at a rate proportional to the concentration of oxygen. Oxygen in the sample gas diffuses through an oxygen specific membrane and is reduced at the cathode. A corresponding oxidation occurs at the anode and an electrical current is produced which is amplified and transmitted to an LCD readout.

Description of Sampling Equipment

The analyzer and sampling system used for this analysis meets the following specifications.

- Analyzer calibration error - Less than ± 2 percent of the span for zero and calibration gases.
- Sampling system bias - Less than ± 5 percent of the span for the zero and calibration gases.
- Zero drift - Less than ± 3 percent of span over the period of each run.
- Calibration drift - Less than ± 3 percent of span over the period of each run.

The CO_2 and O_2 analyzer used by Parsons Engineering Science is an Anarad Model AR-205 Combustion Efficiency Monitor, which measures CO_2 concentration by the IR absorbtion

technique and O_2 concentration using an electrolytic fuel cell. The AR-205 has full-scale range 0-20% CO_2. The CO_2 calibration standards are typically 10-12% and 16-18% CO_2 in N_2

The O_2 analyzer has a range of 0-20.9% and calibration gases of 10-12% and 16-18% O_2 in$N_2$are typically used. Pure nitrogen, or another cylinder gas which contains no CO_2 or O_2 is used to zero the instrument.

The sample is extracted from the duct, conditioned and transported from the sample location into a vented manifold. The sample is then extracted from the manifold by a pump contained inside the analyzer cabinet.

Description of Operation

After the analyzer is calibrated and system bias and leak checks are performed, sample gas is introduced into the instrument. Sampling runs may last from 15 minutes for turbine tests to 60 minutes or longer when done in conjunction with Method 5.

Analyzer responses are determined from a digital data acquisition system which uses an analog to digital signal converter, a personal computer and a hard copy printer. Spread sheet files of all measurements and calibration results are also saved onto a hard disk.

Description of Detection Limits

The flow rate of the AR-205 is 0.5 liters per minute. The analyzer has detection limits of 0.1 percent for both CO_2 and O_2.

Calibration Procedures

After the measurement system is prepared for use, calibration gases are introduced directly into the instrument. The analyzer is calibrated to ± 2 percent of the instrument span for each standard introduced. A gas standard is then introduced into the sample system at the probe to conduct a system bias check. The system bias must not be greater than five percent of the instrument range.

After the sampling run a zero and calibration drift check is performed by introducing a zero and a mid-range calibration gas into the analyzer. If either the zero or upscale value has drifted by more than 3 percent of the span, the run is considered invalid.

In the event that the analyzer fails any of the above tests, the system is diagnosed to determine the source of the problem, corrective maintenance is performed, and the procedure is repeated. All measurements are corrected for bias and drift using equation 3A-1 found in USEPA Method 3A.

SO_2 CONCENTRATION BY USEPA METHOD 6C

Summary of Method

The method of analysis of sulfur dioxide is based upon the absorption of infra-red (IR) radiation by the sulfur dioxide molecule. The intensity of the absorption depends on the concentration of SO_2 present. The IR light beam is split after the light source, with one part passing through the sample cell, and the other part passing through the reference cell, which is filled with a non-absorbing gas. Each beam then passes through a narrow band pass filter (which passes the wavelength of light corresponding to the most intensely absorbing vibration) into photomultiplier tubes for creation and amplification of the signals. The amount of absorbed light (found by difference in signal intensity) is proportional to the amount of SO_2 present.

Description of Sampling Equipment

The analyzer used for this analysis meets the following specifications.

- Analyzer calibration error - Less than ± 2 percent of the span for zero, mid-range, and high-range calibration gases.
- Sampling system bias - Less than ± 5 percent of the span for the zero, and mid- or high-range calibration gases.
- Zero drift - Less than 3 percent of span over the period of each run.

The SO_2 analyzer used by Engineering-Science is a Horiba Model AIA 24 Sulfur Dioxide Analyzer, which operates on the principle of IR absorbtion. The analyzer has full-scale ranges of 0-500, 1,000, 1,500 and 2,000 ppm. SO_2 standards are selected to correspond to approximately 55 and 85 percent of the instrument span range. Gas standards are certified as Protocol-1 by the gas manufacturer. The detection limit of the analyzer is 5 percent of the operating range or 1 ppm when operated on the 0-500 ppm range.

Description of Operation

The full scale range of the analyzer is chosen such that the sample gas concentration corresponding to the applicable emission standard is on-scale, but not less than 30 percent of the analyzer response.

After the analyzer is calibrated and system bias and leak checks are performed, sample gas is introduced into the instrument. Sampling runs may last from 15 minutes for turbine tests to 60 minutes or longer when done in conjunction with Method 5.

Analyzer responses are recorded by a data acquisition system (DAS) which consists of an analog to digital signal converter, a personal computer and a hard copy printer. Analyzer responses are also recorded in a hard disk for subsequent importation into Lotus 1-2-3 for data reduction.

Calibration Procedures

All calibration gases are chosen to conform to USEPA Protocol-1 and are chosen as follows. A cylinder of zero grade air or pure nitrogen is be used as the zero standard. The high- and mid-range gases are SO_2 in air, with concentrations of corresponding to approximately 80-90 percent and 50-60 percent of the full-scale range of the analyzer.

After the measurement system has been prepared for use, the zero and calibration standards are introduced one at a time. The analyzer calibration error check is considered invalid if the response from a single gas differs by more than two percent of the analyzer span.

Immediately before and after each sampling run, a zero and calibration system bias check is performed by introducing zero and mid-range gas into the sampling system at the probe. If either the zero or upscale value exceeds the system bias specification, the run is considered invalid.

In the event that the analyzer fails any of the above tests, the system is diagnosed to locate the source of the problem, corrective maintenance is performed, and the mesurement system is recalibrated according to the procedures outlined previously.

If all checks are satisfactory, the results of the calibration and system bias checks are used to correct the average observed SO_2 concentrations for system drift. The drift correction is performed using equation 6C-1 from Method 6C.

NO_X CONCENTRATION BY USEPA METHOD 7E

Summary of Method

The method of analysis of total oxides of nitrogen (NO_x) is based upon the chemiluminescent reaction between nitric oxide (NO) and ozone (O_3). When these two compounds react, a characteristic wavelength of light is emitted. The light is passed through a photomultiplier tube which amplifies the light beam. The intensity of the amplified light beam is measured by a detector, which converts the light energy into an electronic signal. The magnitude of the signal is proportional to the amount of NO present in the gas sample. The instrument contains an internal source of ozone and a catalytic reduction chamber wherein NO_2 in the sample is reduced to NO prior to its introduction into the reaction chamber. The reduction catalyst may be by-passed, thus allowing for sequential analysis of total NO_x and then NO. The concentration of NO_2 may then be determined by difference.

Description of Sampling Equipment

The analyzer and sampling system used for this analysis meets the following specifications:

- Analyzer calibration error - Less than ± 2 percent of the span for zero, mid-range, and high-range calibration gases.
- Sampling system bias - Less than ± 5 percent of the span for the zero, and mid- or high-range calibration gases.
- Zero drift - Less than 3 percent of span over the period of each run.

The NO_X analyzer used by Engineering-Science is a Thermo Electron Model 10 Oxides of Nitrogen Analyzer, with ranges of 0-2.5, 10, 25, 100, 250, 1,000, 2,500, and 10,000 ppm. Calibration standards are chosen to conform to approximately fifty to sixty percent of span for the mid-range gas, and eighty to ninety percent for the high-range gas. Pre-purified air or nitrogen is used as a zero gas.

Description of Operation

The analyzer is prepared for use according to the manufacturers written instructions and calibrated using the appropriate gas standards. Sample gas is conditioned to remove moisture and allowed to flow into the instrument for the duration of the pre-determined sampling period.

Analyzer responses are recorded by a digital data acquisition System (DAS) which consists of an analog to digital signal converter, a personal computer and a hard copy printer. Responses are also recorded on the computer's hard disk drive for subsequent importation into Lotus 1-2-3 for data reduction.

Description of Detection Limits

The detection limit of the measurement system is typically two percent of the instrument span range. For an operating range of 250 ppm, the instrument detection limit is approximately 5 ppm.

Calibration Procedures

All calibration gases certified by the supplier to conform to USEPA Protocol 1. After the measurement system is prepared for use, the calibration gases are directly introduced into the instrument one at a time beginning with the zero gas. The high- and mid-range calibration gas

are then introduced into the instrument. If the analyzer response to any of the gases differs by more than two percent of the instrument from the predicted response, the calibration error check is considered invalid, the instrument is repaired and the calibration repeated.

Immediately before the sampling run, a zero and calibration system bias check is performed by introducing the zero and mid-range calibration gases into the measurement system. If either the zero or upscale value exceeds the system bias specification, the run is considered invalid.

In the event that the analyzer fails any of the above tests, the system is diagnosed to determine the source of the problem, corrective maintenance is performed, and the entire procedure is repeated.

If all checks are satisfactory, the averages of the zero and span responses to the calibration error and bias checks at the beginning and end of the test are used to calculate the sample concentration for the run the calculation is done using equation 6C-1 of EPA Method 6C.

CARBON MONOXIDE CONCENTRATION BY METHOD 10

Summary of Method

The method of analysis of carbon monoxide is based upon the absorption of infrared radiation by the carbon monoxide molecule, which causes the C-O bond to vibrate in such a manner as to change the dipole moment of the molecule. The wavelength of the absorbed light is dependent upon the difficulty of causing the vibration in question and the intensity of the absorption depends on the concentration of carbon monoxide present. The infrared light beam is split after the light source, with one part passing through a sample cell, and the other part passing through a reference cell, which is filled with a non-absorbing gas. Each beam then passes through a narrow band pass filter which passes the wavelength of light corresponding to the most intensely absorbing vibration into a photomultiplier tube which amplifies the signal. The amount of absorbed light (found by difference in signal intensity) is proportional to the amount of absorbing species present.

Description of Sampling Equipment

The analyzer used for this analysis meets the following specifications:

- Analyzer calibration error - Less than ± 2 percent of the span for zero, mid-range, and high-range calibration gases.
- Sampling system bias - Less than ± 5 percent of the span for the zero, and mid- or high-range calibration gases.
- Zero drift - Less than ± 3 percent of span over the period of each run.
- Calibration drift - Less than ± 3 percent of span over the period of each run.

The CO analyzer used by Engineering-Science is the Bendix Model 8501-SCA Carbon Monoxide Analyzer, which has full-scale ranges 0-50, 0-250, 0-500, and 0-1,000 ppm CO. It is typically operated in the 0-1000 ppm range with standard gases that are 300 ppm, 600 ppm and 900 ppm CO in N_2.

The sample is extracted from the stack, conditioned to remove moisture, and transported to the sample manifold by in inert sample line. The sample conditioning system removes moisture to a dew point of 30°F. Method 10 specifies the use of ascarite to remove CO_2 from the sample, however ES does not typically use ascarite. During calibration, the introduction of twelve to eighteen percent CO_2 into the analyzer demonstrates the absence of CO_2 interference.

Description of Operation

The full-scale range of the analyzer is chosen such that the high range span gas concentration does not exceed 1.5 times the applicable source performance standard at stack conditions.

Analyzer response is measured by a digital acquisition system (DAS), which converts the analog output of the analyzer to digital data which is displayed on the screen of a personal computer. Data is also written to a hard disk file and to a printer.

Description of Detection Limits

The flow rate of the sample gas to the analyzer is self regulated at one liter per minute by a on board pump. The detection limit of the analyzer is two percent of the instrument span, or 20 ppm when operated at the 1000 ppm range.

Calibration Procedures

Zero grade air or pure nitrogen used is used for zero gas. Calibration gases are chosen to be approximately 30, 60, and 90 percent of the instrument's operating range. After the measurement system is prepared for use, calibration gases are directly introduced into the instrument. The analyzer is calibrated and checked to insure that the output differs by no more than two percent of span for each cylinder introduced.

Immediately before each sampling run a bias check is performed on the measurement system by introducing a zero and mid-range calibration gas into the probe. If the system bias check exceeds five percent of the instrument span the system is not used until the problem is repaired. Immediately after each sampling run a bias and calibration drift check is performed to insure that the analyzer drift has not exceeded three percent.

TOTAL HYDROCARBON CONCENTRATION BY USEPA METHOD 25A

Summary of Method

The method of analysis of hydrocarbons is based on the principle that the electrical conductivity of a gas is directly proportional to the number of charged particles present. When hydrocarbons are burned in a hydrogen flame, ionized carbon atoms are produced which decrease the resistance (voltage) across an electrode gap. The resulting voltage decrease is then measured by an amplifier electrometer and recorded on a potentiometric chart recorder.

Description of Sampling Equipment

The sample extraction and analysis for hydrocarbons differs from that of SO_2, CO and NO_X in that no condenser is used to remove moisture from the gas stream. The sample is introduced through a probe, glass fiber filter, a 3-way calibration gas valve, and Teflon® line into a pump within the analyzer. All surfaces that contact the sample gas stream are of stainless steel, glass, or Teflon®, and are heated to prevent condensation of water or organic vapors.

The analyzer to be used for this analysis must meet the following specifications:

- Zero drift - Less than ± 3 percent of the span over the period of each run.
- Calibration drift - Less than ± 3 percent of the span over the period of each run.
- Calibration error - Less than ± 5 percent of the span over the period of each run.

The hydrocarbon analyzer used by Engineering-Science is the J.U.M. Total Hydrocarbon Gas Analyzer which uses a heated Flame Ionization Detector (FID). The J.U.M. has ranges that vary from 0-50 ppm to 10,000 ppm total hydrocarbons, measured as propane ppm total hydrocarbons.

Description of Operation

The span gas concentration is chosen such that it is 1.5 to 2.5 times the expected concentration of the sample or emission limit. The mid-range standard is 45-55 percent of the concentration of the span gas, and the low-range standard is 25-35 percent of the span value. The zeros gas is high purity air with less than 0.1 parts per million by volume of organic material.

After the system is calibrated and all performance checks are completed (see below) the sample gas is introduced into the instrument.

Description of Leak-Check Procedure

Prior to initiation of sampling a three-point calibration is performed on each instrument with the calibration gases injected directly into the instrument. These calibrations are compared

*Teflon is a trademark of E. I. du Pont de Nemours & Company.

to the five-point calibrations that were done in the laboratory to ensure proper instrument calibration. Following these three point calibrations a system bias check is performed for each instrument. This consists of injecting a zero and span gas into the sample conditioning system at the 3-way valve that is mounted at the end of the probe. The response to the span gas injected ahead of the conditioning system must agree within two percent to the response to the same gas injected directly into the analyzer. If this test is passed, the system is proven to be free of leaks and interferences. If the test is failed, then a diagnosis of the system if performed. This diagnosis includes looking for leaks, pools of condensate, accumulations of dirt in the lines or on the filter and checking for instrument malfunctions.

Description of Sample Volumes and Detection Limits

Sample volume does not apply to a continuous monitoring system. The analyzer flow rate is specific to the instrument and may be found in the operator's manual. Where the concentration of organic vapors in the sample gas stream exceeds the capacity of the detector, a heated capillary or critical orifice may be used downstream of the pump to restrict the flow to the analyzer.

Since the span value is chosen to be 1.5 to 2.5 times the expected sample concentration, the detection limit of the method does not apply.

Calibration Procedures

All calibration gases are chosen to conform to USEPA Protocol 1, so verification of the calibration gases is not required. Gas concentrations are chosen as follows. The span gas is 80-90% of the full-scale range, and the midrange standard is 45-55% of the concentration of the span gas.

After the measurement system is prepared for use, the calibration gases are directly introduced into the instrument. The analyzer calibration error check shall be considered invalid if the result for any of the gases is more than ± 2 percent different from the results obtained when compared with the five-point calibration performed at the laboratory.

Immediately after the sampling run, a zero and calibration drift check is performed in the same manner as the system bias check described above. If either the zero or upscale value exceeds the system bias specification, the run is considered invalid.

In the event that the analyzer fails any of the above tests, the system is diagnosed to determine the source of the problem, corrective maintenance is performed, and the entire procedure is repeated.

If all checks are satisfactory, the averages of the zero and span responses from the recorder at the beginning and end of the test are used to calculate the sample concentration for the run.

After a run is successfully completed, the data is transcribed from the strip chart onto the Continuous Analyzer Daily Data form (Figure 2) and the information at the top is completed. The data is then reduced.

A Data Acquisition System may be incorporated in order to obtain the detector output response which provides a hard copy of the results and, the data is also stored on computer.

CASE NARRATIVE

Overview

This project involved the analysis of twelve (12) multi-metal fractions for B, Cr, Mo, Sr, K, and Na. The analysis was conducted according to the protocol described in Method 29: *"Determination of Metals Emissions from Stationary Sources"*. Results reported relate only to the items tested.

Receipt

The multi-metal fractions for this project were received on October 15 and 17, 1994 in good condition in boxes without ice.

Preparation

The samples were prepared by microwave digestion, as required by the contract. Detailed flow charts of the sample preparation are included in the data package.

Analysis

B (boron), Cr (chromium), Mo (molybdenum), and Sr (strontium) concentrations were determined by Inductively Coupled Plasma Emission Spectroscopy (ICP).

K (potassium) and Na (sodium) concentrations were determined by Flame Atomic Absorption (FLAA).

Results

The sample results are reported in μg.

MB

The concentrations of each analyte for this sample are reported in μg/L.

The method blanks for all analytes, with the exception of Na, were less than the respective IDLs. The method blank for Na was greater than the IDL and should be taken into consideration when reviewing the appropriate sample results.

LCS/LCSD

All LCS and LCSD samples demonstrated recoveries within the control criteria of 75-125%.

Duplicate Analysis (D)

Run #1 CU-MMT-01-I FH D:

The duplicate analyses for B, Cr, Mo, Sr, K, and Na demonstrated RPDs within the control criteria of 20.0%.

Run #1 CU-MMT-01-I BH D:

The duplicate analyses for B, K, and Na demonstrated RPDs within the control criteria of 20.0%.

The original and/or duplicate μg/L concentrations of the duplicate analyses for Cr, Mo, and Sr were less than ten (10) times the respective IDLs and cannot be considered valid quality control (QC) qualifiers.

Run #2 CU-MMT-02-O D:

The duplicate analyses for B and Na demonstrated RPDs within the control criteria of 20.0%.

The original and/or duplicate μg/L concentrations of the duplicate analyses for Cr, Mo, and Sr were less than ten (10) times the respective IDLs and cannot be considered valid quality control (QC) qualifiers.

The original and/or duplicate μg/L concentrations of the duplicate analysis for K were less than five (5) times the respective IDL and cannot be considered a valid quality control (QC) qualifier.

Serial Dilutions (L)

Run #2 CU-MMT-02-I FH L:

The serial dilution analyses for B and Mo are valid qualifiers and demonstrated RPDs within the 10.0 % control criteria.

The serial dilution analyses for Cr and Sr are valid qualifiers but demonstrated RPDs outside the 10.0 % control criteria. The high RPDs for these analytes may indicate a significant amount of interferents specific to these analytes in the sample.

Serial dilution analyses for K and Na on the sample Run #2 CU-MMT-03-I FH were not performed since dilutions on the sample were required to determine the concentrations of K and Na in the smaple.

Run #2 CU-MMT-02-I BH L:

The serial dilution analyses for B, Mo, and Sr cannot be considered valid qualifiers since the concentrations of these analytes in the serial dilution samples were less than ten times the respective IDLs. The RPDs for these analytes are reported as "<IDL" in the Analysis Report.

The serial dilution analyses for Cr and K are valid qualifiers but demonstrated RPDs outside the 10.0 % control criteria. The high RPDs for these analytes may indicate a significant amount of interferents specific to these analytes in the sample.

A serial dilution for Na on the sample Run #2 CU-MMT-03-I BH was not performed since dilutions on the sample were required to determine the concentration of Na in the sample.

Run #3 CU-MMT-04-O L:

The serial dilution analyses for Cr, Mo, and Sr cannot be considered valid qualifiers since the concentrations of these analytes in the serial dilution samples were less than ten times the respective IDLs. The RPDs for these analytes are reported as "<IDL" in the Analysis Report.

The serial dilution analysis for K is a valid qualifier and demonstrated a RPD within the 10.0 % control criteria.

The serial dilution analysis for B is a valid qualifier but demonstrated a RPD outside the 10.0 % control criteria. The high RPD for this analyte may indicate a significant amount of interferents specific to this analyte in the sample.

A serial dilution for Na on the sample Run #3 CU-MMT-04-O was not performed since dilutions on the sample were required to determine the concentration of Na in the sample.

Post-digestion Spike Samples (P)

Run #3 CU-MMT-03-I FH P:

The spike recoveries for B, Cr, Mo, and Sr for this sample cannot be considered valid since the spike concentrations added were insignificant in comparison to the concentrations of the analytes in the native sample.

Run #3 CU-MMT-03-I BH P:

All spike samples, with the exception of Cr and Sr, demonstrated recoveries within the control criteria of 75-125%. The spikes for Cr and Sr demonstrated recoveries of 73.7% and 69.7%, respectively, which are slightly outside the control criteria but do not indicate any significant matrix effects specific to these analytes in the sample.

Run #4 CU-MMT-04-O P:

The spike recovery for B cannot be considered valid since the spike concentration added was insignificant in comparison to the concentration of the analyte in the native sample. All other spike samples demonstrated recoveries within the control criteria of 75-125%.

General Comments

Per consultation with Engineering-Science, Inc., the analysis for Cs will be submitted by Galbraith Laboratories in Knoxsville, TN.

The number of pages in this data package is 109

Sample Calculations

$$\text{RESULT in } \mu g \text{ (FH)} = \frac{\mu g/L * \text{ml FV} * DF}{1000}$$

ml FV = final volume in ml,
DF = Dilution Factor.

$$\text{RESULT in } \mu g \text{ (BH \& combined trains)} = \frac{\mu g/L * (\text{ml TV/ml used}) * \text{ml FV} * DF}{1000}$$

ml FV = final volume in ml,
ml TV = total volume in ml,
DF = Dilution Factor.

%REC (Percent Recovery) for spike samples :

$$\%REC = \frac{\text{Spike sample } \mu g/L \text{ conc. - original sample } \mu g/L \text{ conc.}}{\text{spike conc. } (\mu g/L)} * 100$$

RPDs:

$$RPD = \frac{|\text{Result 2 - Result 1}|}{(\text{Result 2 + Result 1})/2} * 100$$
